### 2 ABSTRACT

3 Planning for accessibility is increasingly considered in the development of equitable plans by 4 transport agencies and it has also been shown to exert a positive influence on public transport use. However, this influence has not been examined across income groups and in different geographic 5 regions of varying sizes. The present study measures the relationship between accessibility and 6 mode choice for low- and higher-income groups in eleven Canadian metropolitan regions. Our 7 results show that the impact of accessibility on public transport mode share is stronger and non-8 9 linear for the low-income group especially in the largest metropolitan areas, where increasing accessibility past a certain optimal value will lead to a decrease in public transport mode share. 10 However, this point occurs at the 80<sup>th</sup> percentile of existing accessibility, so improvements in mode 11 share are nonetheless expected with improved accessibility in most areas within these regions. 12 13 Moreover, in regions where an optimal value is not readily observed, improved accessibility throughout the region would lead to increased uptake of public transport for both the higher- and 14 to a greater extent, the low-income group. Findings from this paper can be of value to transport 15 professionals working towards meeting ridership goals around the world as comparisons between 16 17 groups and across regions highlight the variation in the impacts of accessibility on mode share.

18 Keywords: accessibility, equity, public transport, mode share

### 19 1. INTRODUCTION

In recent years, professionals have recognized that the environmental, social and economic 20 21 benefits of public transport compared to personal vehicles are numerous. As such, governments in North America are promoting the use of public transport and often setting goals for ridership (Ville 22 de Montréal, 2008) or mode share (City of Vancouver, 2012) in their plans. In light of these goals, 23 the use of public transport in Canada has risen slowly, from 10.1% in 1996 to 12.4% in 2016 with 24 plateaus observed in recent years (Miller et al., 2018). In some areas, mode share has decreased 25 over the same period (Statistics Canada, 2017). Considering that capital expenditure for public 26 27 transport projects has been rising steadily at a much higher rate since the early 2000's (Canadian Urban Transit Association, 2010, Canadian Urban Transit Association, 2019), one wonders if the 28 29 costs of investing in public transport are appropriate to its use. Also, are these public transport 30 investments going to serve those who would benefit and use it most? The response from 31 researchers in the U.S. (Taylor and Morris, 2015) and the U.K. to these questions is "no" (Banister, 2018) as they argue that there has been a trend of increasing investments in rail transport that is 32 33 geared towards higher-income choice riders. As a result, captive riders, who generally have lower income and are less likely to own personal vehicles, tend to have a limited number of travel options 34 35 (Dodson et al., 2007) and find themselves stranded in the face of reduced public transport services (Giuliano, 2005). 36

For practitioners to begin tackling this inequality in transport, a metric must be defined for 37 which objectives can be set and progress can be tracked against. Researchers have deemed 38 39 accessibility, the ease of reaching destinations (Hansen, 1959), to be an appropriate measure to evaluate the social equity dimension of transport plans (Martens, 2012, Lucas, 2012) through 40 comparing accessibility, as well as its impacts, across income groups. While accessibility to jobs 41 using public transport is known to impact public transport mode share in general (Legrain et al., 42 2015), the impacts of accessibility on public transport use among different groups, to our 43 knowledge, has not been studied yet and should be undertaken from an equity perspective to help 44 in the implementation of policies and projects targeting low-income groups. Furthermore, 45

accessibility is largely influenced by the built environment where regional differences in size, 1 2 structure and public transport system maturity can yield different patterns in accessibility and subsequently, result in differences in the way accessibility affects public transport use. Previous 3 research carried out in Canada was of an exploratory nature and relied on graphical bivariate 4 analyses (Cui and El-Geneidy, 2019) to highlight the relationship between accessibility and public 5 transport use among different income groups and across different geographic regions. In this 6 previous study, a non-linear relationship was identified between accessibility and mode share and 7 was best modelled as a quadratic relationship. Non-linear relationships between aspects of the built 8 environment and commuting outcomes including commuting distance and mode choice by car 9 have also been observed in past research (Ding et al., 2018a, Ding et al., 2018b). 10

The aim of the present study is to build upon the bivariate analysis done previously to confirm and to quantify the impacts of accessibility to jobs on public transport mode share among low- and higher-income groups in these Canadian metropolitan regions, while controlling for other determinants of public transport use. This study will add to the conversation of planning for equitable transport system through accessibility by focusing on the outputs of doing so in regions with different characteristics of the built environment.

#### 17 **2. LITERATURE REVIEW**

18 Whether or not cities in North America are experiencing a public transport renaissance, one thing is for certain - factors that drive public transport use have been of great interest to researchers for 19 some time. These factors can be divided into two major categories: those related to the personal 20 21 characteristics of the traveler and their attitudes and those related to the built environment. Mode choice is highly dependent on personal characteristics such as income (Wang and Woo, 2017), 22 unemployment rate (Lee and Lee, 2013) and proportion of recent immigrants (Taylor et al., 2009). 23 24 Moreover, to capture the combined effects of these highly influential socio-demographic variables, researchers have started using composite variables such as the social deprivation index (Foth et 25 al., 2013). In addition, there is consensus among researchers in Canada, the U.S. and Australia that 26 27 personal vehicle ownership is a major deterrent of public transport use (Boisjoly et al., 2018, 28 Manville et al., 2018, Currie and Delbosc, 2011).

In particular, income is a widely used indicator of social exclusion, transport disadvantage 29 30 and social inequity (Mercado et al., 2012, McCray and Brais, 2007). With respect to mode choice, it has been shown that nationally, low-income groups exhibit higher public transport use than 31 higher-income groups in the U.S. (Giuliano, 2005). In some cases, lower-income users have been 32 33 termed captive users as they have no choice but to use public transport (Beimborn et al., 2003). On the other hand, a study that examined public transport use of low- and higher-wage workers in 34 35 Toronto-Hamilton found that low-wage workers as a group had lower public transport mode share than higher-wage workers (Legrain et al., 2015). However, this contradictory finding could be 36 attributed to the methodology employed to segment workers into wage categories by job sector. 37 The determinants of public transport use specific to lower-income populations has also been 38 explored by researchers such as Mercado et al. (2012) where they found that among low-income 39 40 workers, immigration status, place of work, age, and employment status were significant predictors. 41

Aside from personal characteristics, aspects of land use and characteristics of the public transport system play a role in explaining mode share. Many researchers have found that even when self-selection is accounted for, density, diversity, and design of the urban milieu influence ridership (Cao et al., 2009). In particular, researchers (Chakraborty and Mishra, 2013) have found that higher densities support public transport use better than low-densities whereas Chen et al. (2007) found that in the case of the New York Metropolitan Region, employment density is more influential than residential density. Easy access to a public transport system also impacts mode choice, where being closer to public transport infrastructure, such as stations or stops, increases the odds of its use (Ewing and Cervero, 2010). Accessibility, as the ease of reaching destinations, is used to measure the ease of accessing opportunities using the transport system, thus internalizing aspects of both the built environment, namely density and location of opportunities, as well as availability and quality of transport infrastructure.

Accessibility has also been shown to influence public transport mode share positively (Chow 8 et al., 2006). For example, researchers Owen and Levinson (2015) found, using continuous 9 accessibility to jobs, higher mode share is associated with higher average public transport 10 accessibility in the Minneapolis-Saint Paul area. Moniruzzaman and Páez (2012) found, using data 11 from Hamilton, Ontario that mode share increases as accessibility increases but the relationship is 12 not linear due their use of logit regression models. With this in consideration, and based on the 13 shift we have seen in the past years towards incorporating accessibility as an objective in transport 14 plans (Boisjoly and El-Geneidy, 2017), we identified a need to study accessibility and mode share 15 from an equity perspective to enable a comparison between its impact on public transport mode 16 share at different geographic scales and among different income groups. 17

Moreover, there have been empirical studies done specifically on the distributional impacts of 18 19 existing transport systems (Pucci et al., 2019, El-Geneidy et al., 2016) as well as future projects (Fan et al., 2012) using accessibility. Some researchers sought to compare accessibility of low-20 income jobs for socially vulnerable residents against accessibility to all jobs for the entire 21 population in eleven Canadian metropolitan regions (Deboosere and El-Geneidy, 2018). They 22 identified that while there are geographic differences in accessibility of the two groups, the 23 24 vulnerable tend to experience higher accessibility when compared to the entire population in each 25 region. Furthermore, accessibility has also been studied as a predictor of travel, such as research done on the impact of accessibility on the journey to work (Levinson, 1998). In particular, 26 27 Canadian researchers (Cui et al., 2019a), using data for Toronto-Hamilton, Montreal and Vancouver, found that the influence of accessibility to jobs as well as the presence of worker 28 competition impacts commute duration and is stronger for low-income compared to higher-income 29 30 groups. In addition, the distributional impact of accessibility on employment outcomes were examined for the Los Angeles area where researchers identified that accessibility to jobs by car 31 positively affected the employment status of medium- to low-income groups but not for the lowest 32 33 income group (Hu, 2017).

#### 34 **3. DATA AND METHODOLOGY**

#### 35 **3.1 Study context**

The geographic scope of the present study concerns eleven Canadian metropolitan regions extending from coast to coast as shown in Figure 1. These regions, shown in detail in Figure 2, were selected due to differences in city size, city structure, public transport system maturity, and other socio-demographic factors. As a result, we hope that their inclusion would offer some insight as to how the impact of accessibility differs between regions and among different income groups.

2 FIGURE 1 Context map of the eleven Canadian metropolitan areas being studied

2 FIGURE 2 Detailed comparison of the eleven metropolitan areas

#### 1 3.2 Accessibility and public transport mode share

Accessibility measures used in this study are cumulative-opportunity measures which evaluate the number of opportunities that can be reached from an origin point within a fixed cost, e.g.travel time. As such, the generation of such accessibility measures requires two data inputs: number of low- and higher-income jobs available in each census tract across the eleven regions and public transport travel time between census tracts within each region.

The number of jobs available in each census tract was obtained from the Statistics Canada 2016 7 Commuting Flow tables (Statistics Canada, 2016) which summarize number of work commuters, 8 9 by mode of transport and income bracket, commuting between the their home census tract and the census tract of their place of work. The total number of workers working in a census tract is taken 10 as a proxy for the total number of jobs, excluding unfilled positions which we do not have 11 information about using the Flow tables. A limitation associated with the Commuting Flow tables 12 is that the data has been suppressed for confidentiality purposes. As such, this could lead to some 13 inconsistencies in the results especially where there are low numbers of commuters observed. As 14 we do not know the distribution of the jobs within the census tracts, jobs were assumed to be 15 located at the census tract centroids for which travel time information was also calculated for. 16

17 We chose to define the two income groups in this study as low- and higher-income rather than further defining categories such as medium and high-income groups because we wanted to focus 18 on the results for the low-income group rather than exploring the impacts across an entire income 19 20 distribution. The low-income threshold is defined in this study as the bottom 30% of low paying jobs in each metropolitan region to reflect the local wage distribution. As the Commuting Flow 21 tables categorize commuters by income brackets, the bracket closest to having 30% of the lowest 22 paying jobs is selected as the threshold. A threshold bracket of \$30,000 CAD is used for all regions 23 apart from Calgary, Edmonton and Ottawa-Gatineau where \$40,000 CAD is used. Subsequently, 24 the higher-income group includes commuters from all other income groups higher than the low-25 26 income threshold bracket. Therefore, the number of low-income jobs in a census tract is taken as the sum of all commuters belonging to or below the low-income threshold bracket arriving at that 27 census tract. This was similarly done for the higher-income group. 28

To compute public transport travel time between census tracts centroids within each 29 metropolitan region, General Transit Feed Specification (GTFS) data was first obtained from all 30 public transport agencies operating in each of the eleven regions. Then a joint network between 31 the public transport network and the streets was created using the "Add GTFS to network dataset" 32 33 toolbox in ArcGIS and a travel time matrix for an 8 a.m. departure on a Tuesday was generated using fastest route calculations. Public transport travel time includes access, egress, waiting, in-34 vehicle and transfer times as applicable. In this research we opted to calculate accessibility using 35 one departure time and at the census tract level as the imposed errors from using this method are 36 minor and value added from going into more detail by averaging multiple departures or using 37 smaller geographic areas is minor (Cui et al., 2019b) and would generally harm the transferability 38 39 of the findings to practitioners.

Separate accessibility measures were generated in this study for the two income groups being 40 studied in each metropolitan region. We chose to represent the number of jobs that are accessible 41 42 by individuals in a census tract as a percentage of the total number of jobs that are available in the metropolitan region (i.e. proportional accessibility). This ensures that comparisons can be made 43 between different metropolitan regions. Furthermore, we believe that the use of median travel 44 45 times (as travel time thresholds) specific to each income group in each metropolitan area would further ensure a fair comparison and more realistically reflect the activity spheres and travel times 46 for each group. In addition, the median as opposed to the average would minimize the effects of 47

1 extreme travel times between census tracts in large regions such as Edmonton. Median travel time

2 thresholds are presented in Table 1 and are rounded to the nearest 5-minute interval for use in 3 accessibility measures.

4 Cumulative accessibility measures for the two income groups was calculated separately the 5 jobs and median travel times specific to each group in each region. The measures are formulated 6 as follows:

$$A_{jobs,i} = \frac{1}{\sum_{j=1}^{J} E_j} \sum_{j=1}^{J} E_j f(t_{ij}) \text{ and } f(t_{ij}) = \begin{cases} 1 \text{ if } t_{ij} \le t_{median} \\ 0 \text{ if } t_{ij} > t_{median} \end{cases}$$
(1)

8 where

7

9  $A_{jobs,i}$  = accessibility to jobs from census tract i;

10  $\sum_{i=1}^{J} E_i$  = total number of jobs in a metropolitan region;

11  $E_j$  = number of jobs in census tract j;

12  $f(t_{ij}) =$  a dichotomous function to determine if jobs in census tract j are reachable by census tract i;

13  $t_{ij}$  = commute time by public transport at 8 a.m. between census tracts

i and j; and

15  $t_{median}$  = median commute time used as the travel time threshold.

Lastly, the dependent variable is the percentage of commuters leaving each census tract using public transport out of all commuters. This was computed for low- and higher-income commuters separately. Public transport mode share was obtained from the Commuting Flow tables mentioned previously where public transport includes bus, subway, elevated and light rail, streetcar,

20 commuter train, and passenger ferry.

#### 21 **3.3 Model inputs and development**

22 The regression model is formulated as follows:

23  $PT_{i} = \beta_{0} + \beta_{1}Access_{i} + \beta_{2}Access_{i}^{2} + \beta_{3}Density_{i} + \beta_{4}Age_{i} + \beta_{5}HHstructure_{i} (2)$  $+ \beta_{6}Index_{i} + \beta_{7}Station_{i} + \beta_{8}Highway_{i}$ 

25 where

26 PT = predicted public transport mode share of commuters leaving census tract i;

 $27 \quad Access = A_{jobs,i}$ 

 $28 \qquad Access^2 = A_{jobs,i}^2$ 

- 29 Density = population density in census tract i;
- 30 Age = average age of people living in census tract i;
- 31 *HHstructure* = average household structure in census tract i;
- 32 *Index* = decile ranking of census tract i in terms of social deprivation;
- Station = network distance to the nearest rapid public transport station from centroid of census tract
   i;
- 35 *Highway* = network distance to the nearest highway ramp from centroid of census tract i; and
- 36  $\beta_0, \beta_1, \beta_2, \beta_3, \beta_4, \beta_5, \beta_6, \beta_7, \beta_8 = \text{parameters to be estimated.}$

37 Separate models for each income group in each metropolitan region are generated since 38 different median travel times serve as thresholds to calculate accessibility. The non-linear

relationship described by the quadratic function between mode share and accessibility observed in

- 40 earlier bivariate research (Cui and El-Geneidy, 2019) are shown in the scatterplots in Figure 3. We
- 41 incorporated this quadratic relationship in the regression models through the addition of a squared

- accessibility term (higher-order term) which is the squared value of existing accessibility (lower-order term). 2

FIGURE 3 Scatterplots of public transport mode share and accessibility for both income groups in all regions (Cui and El-Geneidy, 2019)

The road network distance to the closest rapid public transport station (including Bus Rapid Transit stops as well as light, heavy and commuter rail stations) from the centroid of the origin census tract is used to control for the influence of higher quality transport infrastructure on mode share. We defined BRTs based on the presence of dedicated right-of-way and off-board fare payment systems. In addition, network proximity to the nearest highway ramp is also included as the presence of car-oriented infrastructure could impact public transport use negatively (Foth et al., 2014).

Moreover, socio-demographic variables at the origin census tracts, obtained from the 2016 8 Canadian Census, are also included in the regression models. These variables have been studied 9 in previous studies as determinants of public transport use (Miller et al., 2018). We have also 10 elected to use a social deprivation index (in the model) which combines normalized values of 11 household income, unemployment rate, housing affordability, and recent immigration status which 12 has been used previously in studies (Foth et al., 2014). The social deprivation index of each census 13 tract within a metropolitan region is then divided into deciles and entered into the models, with 14 one being least socially deprived to ten being most socially deprived. As we do not have 15 information on the travel attitudes for each commuter, we were not able to control for this in this 16 study. 17

Furthermore, while household vehicle ownership has been found to be influential on public transport use (Miller et al., 2018), this was not available at the census tract level at time of the study. As such, its inclusion in future studies of a similar nature may be beneficial. As well, early trials of the models included the network distance to the city centre as a variable to correct for the effects of spatial autocorrelation by controlling for similarities between census tracts at the same distance from the city centre. However, it was removed from the final model as it was found to be highly correlated with accessibility.

#### 25 **3.4 Summary statistics**

The mean values for the input variables (including variables that make up the social deprivation index) and relevant summary statistics are presented in Table 1.

28 For the majority of the areas being studied, with the exception of London and Kitchener-Cambridge-Waterloo, both average and median commuting times by public transport are lower for 29 low-income groups. Public transport mode share is nonetheless much higher for low-income 30 groups across the country, as observed in past research (Giuliano, 2005). As expected, average 31 mode share is highest in the three largest metropolitan regions with the most developed rapid 32 public transport systems. However, the difference in mode share between other metropolitan 33 regions seems to be unrelated to the existence of rapid public transport systems. For example, in 34 Quebec City, a city without an LRT system, both income groups exhibit higher public transport 35 use when compared with Edmonton, one with an LRT. This confirms that the presence of high-36 quality public transport infrastructure is not the sole predictor of public transport use. Interestingly, 37 active modes are also used by a greater proportion of low-income commuters across all regions. 38 However, when considering higher-income commuters in Halifax, Kitchener-Cambridge-39 Waterloo, and London, we observe that when averaged across each region, a greater proportion of 40 41 commuters use active modes compared to public transport, which is indicative of either a lack of high-quality public transport infrastructure or dense city structures that facilitates the use of active 42 43 modes.

Furthermore, across regions, with exceptions being Kitchener-Cambridge-Waterloo and
 London, average accessibility to low-income jobs is lower than average accessibility to higher income jobs for each metropolitan region. This is in contrast to previous research (Deboosere and

- 1 El-Geneidy, 2018) and illustrates the effect of segmenting the population into low- and higher-
- 2 income groups as well as using time thresholds specific to each income group.

\* Kit-Cam-Wat stands for Kitchener-Cambridge-Waterloo region

#### 1 4. RESULTS

2 The final model outputs are shown in Tables 2, 3 and 4 where regions are grouped based on population and presented as largest-, medium- and smaller-sized metropolitan areas. Since there 3 4 are many models to contend with, the most prominent findings are explained in further detail. In terms of the model goodness-of-fit, a range of values is observed from 0.432 in the higher-income 5 Ottawa-Gatineau model to 0.781 in the low-income Montreal model. There are no observable 6 7 differences between the goodness-of-fits for models segmented by income for the large metropolitan regions. However, the differences are more prominent between models segmented 8 by income for Calgary, Ottawa-Gatineau, Halifax, London and Quebec City, which may be 9 attributed to the absence of factors such as car ownership that could have a greater impact on 10 commuter mode choice in these regions. 11

#### 12 4.1 Accessibility to jobs by public transport

13 The lower-order term of percentage of jobs (Access) accessible by public transport is positively associated with mode share in most regions except for the higher-income groups in Halifax and 14 Kitchener-Cambridge-Waterloo and the higher-order term of the same variable (Access squared) 15 has a negative impact. This result indicates a relationship demonstrated by a concave parabola, 16 where mode share increases in response to increasing accessibility at a non-constant rate until the 17 optimal accessibility value, where a further increase in accessibility has a negative effect on mode 18 19 share. It is possible that the uptake of active modes at locations of very high accessibility by public transport, which can be correlated to high accessibility by active modes, could explain this pattern. 20 A quadratic relationship also means that improvements in mode share due to a one percent 21 point increase in accessibility is different depending on the starting accessibility level. For 22 example, an increase in accessibility from 6% (the mean) to 7% for the low-income group in 23 Toronto-Hamilton will result in a mode share improvement of 2.7 percentage points (an absolute 24 25 increase of 2.7%, not a relative increase) compared to an improvement of 1.1 percentage points when accessibility is increased from 13% (one standard deviation above the mean) to 14% in the 26 same region. Moreover, the optimal value for this model is reached when the percentage of jobs 27

that are accessible is 18% (89<sup>th</sup> percentile) where maximum public transport mode share is expected but any further increase in accessibility would cause the mode share to decrease. It is important to note that 18% may seem low, but this is three times greater than the mean value of 6% for the low-income Toronto-Hamilton model. The optimal values for the low-income models in Montreal and Vancouver are also much higher than the mean and occurs when accessibility is at the 87<sup>th</sup> and 81<sup>th</sup> percentiles respectively.

34 The lower-order accessibility term is statistically significant at 95% in most models but the higher-order term is significant in fewer models. In addition, the magnitudes of both of these 35 coefficients in the low-income models are highest in the three largest metropolitan areas. The 36 average value of the lower-order accessibility term for the low-income group in these three regions 37 is 2.470 compared to 0.383 in the others; the average value of the higher-order term is -0.057 38 39 compared to -0.004. In the higher-income models, the coefficients of the lower order term are also highest for these three regions with an average of 0.645 compared to the others with an average 40 41 value of 0.148. This may suggest that the non-linear relationship as modelled by a quadratic relationship between accessibility and mode share is most profound in the largest metropolitan 42 areas. In contrast, the quadratic relationship between accessibility to jobs by public transport and 43 public transport mode share is not strongly observable for either income groups in Calgary, 44 45 Halifax, Kitchener-Cambridge-Waterloo and Winnipeg as indicated by the insignificance of the two variables. Furthermore, as the optimal accessibility values are not yet reached in the higher-46

income Toronto, Montreal, Vancouver, and Winnipeg models in addition to the low-income Kitchener-Cambridge-Waterloo, Ottawa-Gatineau and Quebec City models (i.e. optimal value falls outside of the observed range of values), the phenomenon of decreasing mode share past the optimal accessibility value may not hold true for these groups of commuters. In light of these observations, it seems that the non-linear quadratic relationship is mostly applicable for the lowincome models for the three large metropolitan regions, Edmonton and London in addition to the higher-income Ottawa-Gatineau and Quebec City models.

In addition, we observe that the coefficients for accessibility are always higher (in terms of 8 magnitude) in the low-income models compared to the higher-income ones, with the exception of 9 Halifax where the effects are similar and Kitchener-Cambridge-Waterloo where the pattern is 10 inversed. This implies that accessibility by public transport influences mode share more strongly 11 for the low-income group compared to the higher-income group while controlling for the same 12 socio-demographic and spatial variables. Specifically, this result indicates that every percentage 13 point increase in accessibility results in a greater increase in public transport mode share for the 14 low-income group than the higher-income. 15

Furthermore, it is important to note that a one percent increase in job accessibility in Toronto-16 Hamilton is not equal to the same percent increase in a smaller city. For example, a one percent 17 increase of low-income jobs accessible in Toronto-Hamilton is equivalent to an increase of 8,000 18 jobs whereas in London this equates to 600 jobs, which is unlikely to have impact on public 19 transport mode share. However, when the same models are run with all other variables held 20 constant but using the number of jobs accessible rather than the percentage (shown in Table 5), we 21 see that the magnitudes of the coefficients are higher in smaller regions like London where a 22 10,000 increase in jobs accessible by public transport would have a greater impact on mode share. 23 24 For example, an increase in accessibility from a mean of 13,942 low-income jobs to 23,942 in 25 London results in a 5.1 percentage point increase in low-income mode share whereas in Toronto-Hamilton, an increase from a mean of 53,268 low-income jobs to 63,268 results in an increase of 26 27 3 percentage points in mode share.

#### 28 4.2 Other control variables

The most influential control variables across all models include the social deprivation index (Social 29 *Index*) and the network distance to a rapid public transport station (*Station*). The social deprivation 30 index has a positive influence on public transport mode share (i.e. higher level of social deprivation 31 is correlated with higher use) across all models, confirming results from past research (Foth et al., 32 2014). It is clear that low-income individuals living in more socially deprived census tracts are 33 more likely to use public transport rather than high-income individuals in a similarly socially 34 35 deprived census tract. As expected, as distance from a rapid rail station increases, public transport mode share is 36 likely to decrease for both income groups (Cervero et al., 2010). The relationship between network 37

distance to the closest highway on-ramp and mode share is mixed, as it is significant and positive
for the higher-income group in Calgary, Edmonton and Toronto-Hamilton but negative for both
income groups in Vancouver, Halifax and Quebec City, and would require further investigation.

## TABLE 5 Model results using accessibility as number of jobs accessible for all metropolitan regions

#### 1 5. CONCLUSION

To our knowledge, this is the first study to compare the impacts of accessibility on mode share between low- and higher-income groups for numerous metropolitan regions of varying sizes. To do so, we carried out a series of linear regression models using accessibility to jobs by public transport while accounting for other control variables to model public transport mode share for departing commuters at the census tract level. The results confirm the importance of planning for accessibility to impact mode share, particularly for the low-income group, while demonstrating discrepancies between metropolitan regions.

Firstly, we confirm that a greater proportion of people in the low-income group use public 9 transport as their main commute mode in all study areas, similar to past research (Giuliano, 2005). 10 Next, more socially deprived census tracts exhibit higher public transport use and shorter distances 11 to rapid public transport stations positively influence mode share. Most importantly, we find that 12 accessibility is a predictor of mode share as previous researchers have shown (Moniruzzaman and 13 Páez, 2012), although our characterization of this relationship as quadratic may not be applicable 14 to all metropolitan regions. The relationship between the two variables is more strongly observed 15 in the largest metropolitan regions. A notable result is income does moderate the relationship 16 17 between accessibility and mode share in that it has a higher predicting power of mode share for the low-income group than higher-income groups in the majority of the studied regions. In other 18 words, public transport use by the low-income group is more sensitive to changes in accessibility 19 20 than the higher-income group.

Furthermore, while these results imply that we would expect significant gains in public 21 transport mode share for low-income groups in the largest metropolitan regions, we need to be 22 mindful that at very high levels of accessibility, increasing accessibility is not expected to lead to 23 a substantial increase in use due the non-linear relationship observed between accessibility and 24 mode share. However, since the percentage of jobs accessible in a census tract would have to be 25 in at least the 80<sup>th</sup> percentile in these regions for this to be applicable, improvements in mode share 26 are still expected in the majority of the census tracts where the accessibility is currently below this 27 value. Moreover, for metropolitan regions where the quadratic relationship is not strongly 28 29 observed and there is no optimal value, we can expect an increase in mode share for the lowincome, and to a lesser extent, the higher-income groups with improved accessibility throughout 30 the region. 31

With these findings in mind, policies that would greatly improve the accessibility for low-32 33 income groups would bring about a greater increase in public transport use. Doing so would also mean that low-income riders who are more likely to be reliant on public transport will benefit from 34 the service improvements, which can make a greater impact to improve their quality of life. As a 35 first step, ridership profiles can be created for the public transport network in a region to identify 36 routes that are mostly frequently used by low-income commuters. These can be targeted for service 37 improvements to improve accessibility and potentially result in more public transport use based 38 on our findings. In addition, a return on public transport investments can be expected when they 39 are aimed at improving accessibility in areas of low existing accessibility rather than highly 40 accessible ones. Furthermore, the findings of our research can help policy-makers determine the 41 42 approximate optimal accessibility value at which public transit use may be maximized based on the values of the input variables specific to a census tract and the results of the regression analysis 43 in this study. 44

Further examination of the relationship between accessibility by active modes and public transport mode share is necessary to confirm our hypothesis that the decline in mode share at very

high levels of accessibility is attributed to the uptake of walking and cycling. Doing so could also 1 2 help explain the inconsistent results that were observed in the higher-income Halifax, Kitchener-Cambridge-Waterloo models. Moreover, while this model used a quadratic function to model the 3 non-linear relationship, understandably this may not be the best function to use to fit the data in 4 every metropolitan region but was done for the sake of comparison. Future studies can employ 5 more advanced methods to describe the relationship more appropriately. In addition, the effects of 6 temporal variability of public transport on accessibility can be addressed in the future studies by 7 using an average accessibility value to be entered in the models described in this study. As well, 8 other regressions models may be employed to model public transport use such as a binomial 9 regression model for the proportion of commuters that use public transport. 10

This study also highlights the importance of context-specific research. Namely, this study 11 raises important questions, especially with respect to smaller metropolitan regions. Firstly, the 12 quadratic relationship is not observed for all income groups and not in all the metropolitan regions. 13 As such, other relationships can be explored between accessibility and mode share that may 14 improve the model fit and yield more meaningful interpretations. In addition, the small number of 15 census tracts in Halifax and Kitchener-Cambridge-Waterloo could explain the inconsistent results 16 observed in the models for these two regions. Further investigations in these areas may benefit 17 from using information at a smaller geographic scale than census tracts. Furthermore, while 18 19 income is one indicator of socio-economic status, similar comparisons to what was done in this study can be made for groups in society based on other attributes of socio-economic status to reveal 20 the travel preferences of these groups change with respect to accessibility. These analyses can offer 21 new insight to help practitioners approach transport planning in a more equitable manner while 22 ensuring good returns on investments. 23
